
What the Final Patch Hides: Event-Level Regression Measurement for Coding-Agent Harnesses

Abstract

1 When a coding agent is graded, only its final patch is examined. We asked what
2 happens in between: does the agent break the repository’s existing tests while it
3 works, and does the final patch show it? We built an instrument that snapshots
4 the working tree after every edit and re-runs the repository’s previously-passing
5 tests at every snapshot inside the benchmark’s own container. In a pilot on 40
6 SWE-bench Verified tasks, agents broke previously-passing tests 184 times along
7 the way; the final patches showed one of those breaks. Whether this happens
8 depends on the model more than on the task: on the same tasks and harness, one
9 frontier stack never broke a test and another did so 140 times. Rolling back to the
10 last verified checkpoint keeps the final tree clean but costs solved tasks, because
11 the check that triggers the rollback rejects correct patches. Gating each step on the
12 repository’s own tests instead removes that cost: 65% solved with no contaminated
13 final tree, and 70% when the gate is graded on tests it never reads. We release the
14 instrument, its validation protocol, and a catalogue of 28 measurement defects met
15 while building it, 23 of which produced plausible numbers rather than errors.

16 1 Introduction

17 Benchmarks for coding agents grade the final patch. SWE-bench [1] and its Verified subset [2] apply
18 the patch an agent submits, run the repository’s tests, and report whether the target tests now pass
19 and the previously passing tests still pass. Work on regressions caused by agents follows the same
20 convention and counts the previously-passing tests the submitted patch breaks [8].

21 That convention cannot see what happens while the agent works. An agent that breaks an existing test
22 at step three and repairs it at step five submits a clean patch; any harness with a recovery mechanism
23 produces that pattern by design. Two basic questions therefore have no answer: how often do agents
24 break existing behaviour during a run, and how much of it survives to the final patch?

25 We answer both by measuring the timeline instead of the endpoint. Every mutating tool call becomes
26 a commit on a git reference the agent cannot see; after the run, the repository’s previously-passing
27 tests are re-run at every commit inside the benchmark’s pinned container. This is the observation
28 primitive an agent operating system needs before it can build a recovery primitive. Our contributions
29 are:

- 30 1. **An instrument for event-level regression measurement.** Every mutating tool call is
31 recorded as a commit on a git reference the agent cannot see; after the run, the instance’s
32 held-out passing tests are replayed at every recorded state inside the benchmark’s pinned
33 container, and detection is attributed by coverage. Validity is established by controls, a

liveness gate, a golden check through the agent’s own execution path, and a re-scoring control (Section 3).

2. **Measurements on SWE-bench Verified.** Across the GPT-5.6 rollback runs that produced any regression, the timeline recorded 184 events and the final state exposed one (Section 5.2). Event frequency depended on the model stack: identical instances and harness gave 0 events under one frontier stack and 140 under another (Section 5.3).
3. **A pre-registered comparison of recovery policies, and a fix.** With the analysis committed before unblinding, rollback to a verified checkpoint left fewer contaminated final trees than no recovery ($p = 0.022$) but resolved fewer tasks; we trace the loss to verifier precision, and a post hoc regression-gated verifier, enforced by the harness at every step, removes it: 65% resolve with no contaminated tree, 70% in a split variant graded on tests the gate never reads (Sections 5.4 to 5.6).
4. **A catalogue of 28 measurement defects** found while building the instrument, classified by mechanism (Appendix A); 23 produced a plausible number rather than an error.

All measurements are exploratory and were made on a development slice of the benchmark that is excluded from any confirmatory frame. No claim is made about the population of instances beyond that slice.

2 Background and related work

Benchmarks and their validity. SWE-bench [1] grades a patch by tests that must go from failing to passing and tests that must keep passing; Verified [2] is the human-screened 500-instance subset. Concerns about the static subset have accumulated: contamination, memorisation, and leaked solutions [6], flawed tests [7], and rolling [3, 5], private [4], or long-horizon [23] alternatives in response. UTBoost [7] found the held-out tests often insufficient: augmented tests exposed 345 mislabelled patches, affecting 24.4% of Verified leaderboard entries. Wang et al. [37] find resolve rates on Verified overstated by 6.2 points once plausible-but-wrong patches are inspected. TDAD [8] measured regressions in submitted patches on Verified (6.1% of runs under a vanilla open-weight agent) and reduced them with a pre-change impact-analysis map that tells the agent which tests to verify. Process-level benchmarks have begun to score intermediate states: RigorBench [35] scores per-state test stability on 30 curated tasks from logs, SWE-CI [36] tracks regressions across CI iterations of its own tasks, and AgentLens [38] names regression cycles as a lucky-pass mechanism in 10.7% of passing OpenHands runs, from logs alone. We measure the same quantity at every mutating call on standard Verified instances, by executed replay, and attribute each event to the check that could have caught it.

Agent scaffolds and recovery. SWE-agent [9], OpenHands [10], Agentless [11], and mini-swe-agent [12] span the scaffold design space, built on CodeAct [13] and ReAct [14]. Within-episode recovery has been studied as self-reflection [15, 16], progress-gated recovery [17], checkpoint repair [18], provenance-based rollback [19], and aligned context-and-environment checkpoints [41]. Closest to us, Kim et al. [39] re-execute intermediate edits of 16,758 trajectories, find agents that reach a gold-identical patch and then destroy it, and recover those cases with an edit-commit checkpoint; Gao et al. [40] bind verifier evidence to exact code states and preserve verified checkpoints on function-level repairs. Neither counts regressions or compares recovery policies. Running the repository’s regression tests during a run is deployed practice: TestPrune [43] hands the agent a minimised suite it may call, for an 8 to 13% relative resolve gain across three scaffolds, and Trae Agent [44] filters candidate patches with regression tests. Operating-system framings [20] move scheduling, context, memory, and storage into a kernel for agents, and a branch-context primitive [42] gives fork, commit, and abort semantics over filesystem and process state; neither observes the tree between actions. Process reward models and rubric verifiers [24, 25] approach the verifier-precision problem of Section 5.5 from the reward and test-time-selection side.

Automated program repair. The regression problem is the plausible-versus-correct patch problem of program repair [26, 28, 29]; regression tests are the main defence against overfitting patches [27]. Our results concern regressions the agent’s own process repairs before the patch is tested; trajectory-level evaluation [21, 22] argues that resolve rate alone is uninformative. Public leaderboard trajectories record actions but not the tree at each step; the instrument commits the tree.

Figure 1: The harness and the instrument. The planner, worker, monitor, and recovery policy run inside the benchmark’s pinned container; every mutating tool call commits the tree to a hidden git reference, and after the run the instance’s previously-passing tests are replayed at every state. The test row shows one such test regressing at s_3 – s_4 and repaired by a rollback to s_2 , which the official grader, reading only s_n , never sees. In the gated arm (dashed), the timeline’s tests serve as the monitor.

3 Instrument

Figure 1 shows the harness and the instrument. **Observational timeline.** After every mutating tool call, the working tree is committed to a git reference outside the agent’s view, using a private index so that the agent’s own `git status` and `git diff` are unchanged. Rollbacks and the end of the run are observations too, and because observations are commits, an archived run can be re-measured later without re-running the agent.

Exhaustive replay. For each observation, the instance’s passing-test set is run inside the pinned container against that observation’s tree; a regression event is a test that passes at one observation and fails at a later one. Every observation is replayed rather than bisected: a recovery policy makes verdicts non-monotone. Replay is scoped to the files holding the held-out tests, which is what keeps it affordable: 4 to 8 seconds per observation on the two repository families we timed (pytest and django), about 26 CPU-minutes for a 40-instance sweep, and a projected 80 CPU-hours for 500 instances at 100 edits each. Infrastructure failures during replay are recorded as missing observations rather than as test failures, and baseline-dead tests are excluded from event counting.

Attribution. A detected regression is classified three ways: *attributed* if a failing harness check and the broken held-out test both exercise a file the agent changed at that observation (using a per-instance coverage map built at the base commit), *co-occurring* if some harness check failed while the regression was open but no such link exists (an over-count of detection), and *unknown* if the coverage map cannot say.

Execution environment. The agent’s tools and the harness’s checks execute inside the same pinned container as the replay, with file changes synchronised to the host tree the timeline records (Appendix A.2).

Validation. Five gates run before any paid experiment: a negative control, a positive control with injected regressions including recovered ones, a flake screen, an unknown-rate ceiling, and a baseline liveness check. A golden check drives the gold patch through the agent’s real tool path and requires the grader to return “resolved” (a null run “unresolved”); it passed on three repository families. A re-scoring control re-measures an archived timeline under a changed instrument with no model calls; on both runs to date it reproduced the archived episode counts.

4 Experimental setup

Benchmark and slice. SWE-bench Verified, 500 instances. It is no longer a capability benchmark: its maintainers’ audit found saturation, contamination, and tests that reject correct patches [46]. We use it as a substrate, not a leaderboard: its pinned images and previously-passing test sets make the measurement possible. A 40-instance development slice (16 from django), stratified and fixed before any measurement, was used throughout and is excluded from any confirmatory frame; the GPT-5.6 stack also ran on its first 10 instances as a calibration, and plain rollback ran twice. SWE-bench Live [3] is the second substrate: a rolling set of post-cutoff instances built monthly from live repositories and graded by its own harness, whose rules we mirror (an xfail counts as a failure; a test missing from the log blocks nothing). Its slice was fixed before any outcome: pytest-parsed instances with 27 to 3,000 previously-passing tests, at most four per repository, earliest first, the first 40 of 48 candidates that passed a \$0 environment check. Live oracles are about twenty times Verified’s (median 1,711 previously-passing tests), and no coverage maps are built for Live, so attribution there is unknown by construction.

Harness. A planner decomposes the task into steps with verification commands; a worker executes each step with three tools (read, write, shell); a monitor runs the verification, and on failure the recovery policy acts: **rollback** (reset to the last verified checkpoint, retry with feedback), **repair-in-place** (retry from the failed tree), or **no recovery** (keep the failed step’s tree). Runs have a \$4 work-cost cap; exhaustion scores as failure.

Models. Two frontier stacks under identical harness, policy, instances, and caps, named by their API model strings: `claude-opus-4-7` (planner) with `claude-sonnet-4-6` (worker), and `gpt-5.6-sol` (planner) with `gpt-5.6-terra` (worker), recorded in every run manifest.

Outcomes. Resolve is the official grader’s verdict on the final patch. Events are reported at three levels because the distribution is overdispersed: distinct incidents (observations at which at least one test broke), declared events (one per test function and onset, parametrised variants collapsed), and bearing runs. Final-state contamination is the number of held-out tests failing in the graded final patch, net of baseline-dead tests.

Pre-declaration. The event unit, the gates, and the contrast were declared before the relevant data existed; the contrast’s analysis (exact paired sign tests, final-state contamination primary, incident exposure co-primary) was committed before either comparison arm finished; one amendment, making the gates conditional on the model stack, preceded unblinding (Appendix B).

5 Results

5.1 Resolve and cost

Under rollback, the Claude stack resolved 13 of 40 instances (32.5%, exact 95% CI 18.6% to 49.1%) for a total sweep cost of \$34.24; the GPT-5.6 stack resolved 13 of 40 (32.5%; 13 of the 35 graded, 37.1%) for \$8.14. Three GPT-5.6 cells were never attempted (circuit breaker) and two were lost to a file-synchronisation defect; all five count as unresolved out of 40 and are excluded from the graded denominator. One instance cannot be resolved by any arm under the current official parser (Appendix A.3), so every rate has a ceiling of 39. Runs are short: the median run makes 5 mutating tool calls (IQR 4 to 8, maximum 19 over 235 runs; 94% make 10 or fewer), an order of magnitude below public-scaffold trajectories.

5.2 The final state hides almost all regression activity

Figure 2 shows every run that produced a regression event under the GPT-5.6 stack with the rollback policy, pooling the 10-instance calibration and the 40-instance sweep (47 runs). The timeline recorded 184 declared events across eight runs; the final patch exposed one. Run-weighted, seven of the eight bearing runs ended with a clean final patch; three storms (73, 48, and 41 events) supply 88% of the event count, so the run-weighted figure is the more robust statement.

Figure 1’s test row is one such run: three regressions of the same test function, each repaired by rollback two observations later, two of them undetected by any harness check while open. Across the full GPT-5.6 sweep, 48 of 162 raw episodes had no co-occurring harness failure.

Figure 2: Every run that produced at least one regression event, in both GPT-5.6 sweeps: events recorded on the timeline (red) against held-out test failures visible in the graded final patch (grey).

Figure 3: The five recovery arms under the GPT-5.6 stack on the same 40 instances (split: the split-oracle gate). Contamination counts cells whose final patch fails a previously-passing test.

5.3 Regression frequency depends on the model stack, not the benchmark

On the same 40 instances, under the same harness and rollback policy, the Claude stack produced no regression events in 40 runs (227 observations, all replayed). The GPT-5.6 stack produced 140 declared events in 11 incidents across 6 of 37 attempted runs (bearing fraction 16.2%, exact CI 6.2% to 32.0%). A one-sided Fisher exact test on the bearing fractions gives $p = 0.010$; this is a single pairwise test on six bearing runs (reassign three of them and $p = 0.11$), and the two stacks also traverse different provider adapters. Observation density differs only by $1.2\times$. The two stacks resolved the same number of instances (13 of 40 each) for total sweep costs of \$34.24 against \$8.14: the stack that never broke adjacent behaviour cost four times as much per run. The three storms that supply 88% of the events are model edits (six lines in seaborn, nine in django, a 262-line deletion in flask), none truncated or from a capped turn.

The Claude zero is measured, not a detection failure: the same stack’s earlier canary run produced three events, and re-scoring its archived timeline under the sweep’s instrument reproduces them.

The pre-declared event-rate gate failed for both stacks, so no arm here is a confirmatory pass (Appendix B); we claim no more than a single-sweep dependence on the model stack.

5.4 Recovery policy: rollback keeps the final tree clean

Figure 3 summarises the pre-declared contrast. The primary endpoint, final-state contamination, is paired by instance: no recovery was worse than rollback on 9 instances, better on 1, and tied on 25 (exact sign test, $p = 0.022$). Repair-in-place was worse on 5, better on 1, and tied on 29 ($p = 0.22$). The co-primary endpoint, incident exposure, did not differ detectably (no recovery $p = 0.45$; repair-in-place $p = 1.0$): regressions occurred at similar rates under every policy; the policy determined whether they persisted.

Disclosure. The first unblinding gave $p = 0.375$. Seven cells (five no-recovery, two repair-in-place) whose final trees made the suite uncollectable had been dropped as ungradable, removing the most contaminated states from the endpoint; official grading scores such a patch as failing every test. The grader was corrected to distinguish an environment failure from a patch that kills the suite, and the

191 seven archived trees were re-graded without re-running any agent, giving $p = 0.022$. The rule changed
192 after the data were seen (Appendix B).

193 5.5 Rollback loses resolution to verifier precision

194 Rollback resolved fewer tasks than either alternative (Figure 3, left): 13 of 40 against 24 (repair-
195 in-place) and 22 (no recovery); paired by instance, it won one discordant pair and lost nine against
196 repair-in-place (McNemar exact $p = 0.022$) and won three and lost nine against no recovery ($p =$
197 0.15). The loss is attributable to the verifier: of the 18 rollback runs that failed, 15 failed at the first
198 step, and 9 of the 18 were resolved under a policy that kept the rejected work: the planner-written
199 check had rejected a patch the grader accepted, and rollback discarded it.

200 5.6 Regression-gated rollback removes the tradeoff

201 A fourth arm, added after unblinding and therefore exploratory, replaces the monitor’s planner-written
202 check with the repository’s previously-passing tests, run in the agent’s container at the start and
203 after every attempt; a step is rejected only if a test that passed at the start fails now. It resolved
204 **26 of 40 instances (65.0%)**, the most of any arm and the level frontier scaffolds reach ungated
205 [39, 44], with **no contaminated final tree** (Figure 3). Paired against plain rollback on the 35 shared
206 instances, it resolved 10 that plain rollback did not and lost 1 (McNemar exact $p = 0.012$; post hoc,
207 unadjusted; onset exposure $p = 0.73$). The gate’s tests come from benchmark metadata: its baseline
208 oracle coincides with the grading oracle (median ratio 1.00), so clean final trees are guaranteed
209 by construction, and the selection itself observes roughly the gold test patch’s blast radius, which
210 a deployed agent lacks. The deployed analogue gates on the full suite at baseline (django’s takes
211 about two minutes per attempt against 4 to 8 seconds scoped) or on a metadata-free selector such as
212 TDAD’s map [8]; the gated rates are upper bounds on either. A fifth arm, a split variant, removes
213 the guarantee: the gate reads a deterministic half of the previously-passing ids (2,278) and never the
214 other half (2,585), on which the grader rules; reading only previously-passing tests also rules out
215 overfitting to a visible target test [45]. It resolved **28 of 40 (70.0%)**, indistinguishable from the full
216 gate (5 discordant pairs to 3, $p = 0.73$) and 13 pairs against 2 over plain rollback (McNemar exact $p =$
217 0.007), with no final tree failing a held-out test, net of the parser-capped instance of Section 5.1. A
218 second plain-rollback sweep reproduced the first (13 and 13 resolved; 6 of 37 bearing both times).
219 Gating on the repository’s tests is deployed practice [43, 44]; what is added is harness enforcement at
220 every step rather than a skippable tool, contamination measured beside resolve, grading on tests the
221 gate never reads, and the location of rollback’s loss in its verifier.

222 6 Discussion

223 **Why timeline regressions matter.** A regression the agent repairs before submission did not reach
224 the user, but it is not free: 27% of spend across the eight bearing runs (\$0.63 of \$2.33) went to work
225 done while a regression was open. The events are the per-step ground truth process reward models
226 [24, 25] need; for agent-OS design, a branch context [42] supplies fork, commit, and abort, and the
227 timeline tells a policy when to abort.

228 **Summary.** Final-state evaluation misses the regressions an agent’s own process repairs, nearly all of
229 them here; the timeline measurement is feasible, separates recovery policies the final patch cannot, and
230 locates rollback’s cost in verifier precision. Building the instrument produced 28 defects (Appendix
231 A); two rules would have prevented most: record infrastructure failures as missing observations, and
232 require a positive liveness signal.

233 7 Limitations

234 All measurements come from a 40-instance slice, one sweep per arm (two for GPT-5.6 rollback).
235 The cross-stack comparison rests on six bearing runs, confounded with the provider adapter; the
236 gated arms are post hoc and select tests from benchmark metadata. Runs are ten times shorter than
237 public-scaffold trajectories (median 5 mutating calls), and the ungated 32% baseline is far below
238 frontier scaffolds’. The held-out tests observe roughly the gold test patch’s blast radius, so event
239 counts are lower bounds; a public-scaffold run comes next.

A The measurement defect catalogue

Two rules would have prevented most of the defects below: record infrastructure failures as missing observations, and require a positive liveness signal.

A.1 The catalogue by mechanism

Each row is a defect found while building the instrument. **S**: it produced a plausible number rather than an error. **G**: it was present while the test suite passed (A4 is the suite). **H**: it was findable only on a clean host. Class A rows depend on the machine the code runs on; class B rows render an infrastructure failure as a measurement; class C rows measure a state where an event was defined; class D rows consume a producer’s output without checking the producer.

#	Defect	Consequence	S	G	H
A1	Shadow commits inherited the machine’s git identity	timeline silently empty on any clean machine	✓	✓	✓
A2	Gate probe invoked bare <code>python</code>	every probe exit 127 on a clean host	✗	✓	✓
A3	Unpinned SDK resolved a different major version	two machines ran different code	✗	✓	✓
A4	Test fixtures verified with bare <code>pytest</code> from <code>PATH</code>	15 tests fail on a clean host as harness defects	✗	—	✓
A5	A benchmark scorer invoked bare <code>python</code>	score 0.0 from a missing interpreter	✓	✓	✓
A6	Agent executed on the host; measurement in the container	26 of 28 zero-step runs; see A.2	✓	✓	✓
B1	Output marker used shell :	a 13/13 run scored as 13 errors	✓	✓	
B2	Results on <code>stderr</code> , markers on <code>stdout</code>	one framework’s results outside the parsed slice	✓	✓	
B3	Probe diffed against a deleted commit	every graded test a hole	✓	✓	
B4	Interrupted mirror clone accepted with zero commits	later instances fail far from the cause	✓	✓	
B5	Container <code>workdir</code> unvalidated	every <code>exec</code> exit 127	✓	✓	
B6	Isolation removed loopback, not only the internet	23.5% of the oracle dead	✓	✓	
B7	Provider cache served removed containers	later cells replay against nothing and score clean	✓	✓	
B8	Tree reset reverted image build-time edits	one repository family’s oracle dead	✓	✓	
C1	Bisection assumed monotone verdicts	recovered regressions invisible	✓	✓	
C2	Declared event unit not implemented	rate off by up to 2.7×	✓	✓	
C3	Rollbacks produced no observation	recoveries invisible to the timeline	✓	✓	
C4	"Persists past the step boundary" undefined	one reading excludes the events of interest	✓	✓	
D1	Audit field never populated	0 tool errors reported, always	✓	✓	
D2	Malformed planner output crashed the run	33% of runs lost as task failures	✗	✓	
D3	Dependency install counted as agent work	attribution vacuous	✓	✓	
D4	Join took the first observation, not the last	failures pinned to the wrong tree	✓	✓	
D5	Executed config rebuilt from a name	manifest described a different run	✓	✓	
D6	Git handles never released	sweeps die after ~400 cells	✓	✓	
D7	Console re-walked the tree per run	presented as a dead server	✗	✓	
D8	Detection events lacked the ids attribution joined on	attributed detection always unknown	✓	✓	
D9	Absent coverage rendered as measured silence	unmeasured episodes reported as silent	✓	✓	
D10	Output-capped turns executed	half-written file; a 78-event storm	✓	✓	

Totals: 23 of 28 silent; 27 of 28 present under a passing suite; 6 of 28 findable only on a clean host. Seven further defects found after this census closed are described where they arose (Section 5.4, Appendix A.3, and the repository log).

A.2 The defect that invalidated a conclusion

After nineteen fixes, every validation gate passed, the re-scoring control reproduced archived episode counts exactly, and three pilots (80 runs) measured an event rate far below the pre-declared gate. We drafted the conclusion the rule directed: the benchmark offered too little opportunity, so switch benchmarks. The conclusion was wrong. The harness ran the agent on the host in a bare source

checkout, while every probe and every gate ran inside the pinned container. On the host, `import matplotlib` in that checkout succeeds by importing the uncompiled source tree as a namespace package, and everything downstream fails in ways indistinguishable from an incompetent agent. Twenty-six of 28 zero-step runs traced to this. The gates had validated the measurement path and never the agent’s execution path. The fix was to route the agent’s tools and checks through the same container as the replay, and to add a per-cell environment parity check that runs before any model call.

A.3 Mechanisms in public infrastructure

Class A: OpenHands issues #4235 and #7044 [31], environment construction failures against SWE-bench images. Class B: UTBoost’s finding that the held-out oracle is insufficient at leaderboard scale [7], and, on SWE-bench Live, baseline tests that fail in the unmodified image because the calendar passed a deprecation date encoded in the instance. Class C: final-state regression measurement [8]. Class D: the SWE-bench grader accepting forged test output on stdout [30], and, at the harness’s current revision, a parser that keys parametrised ids by their full text while the dataset stores them truncated at the first space (the earlier parser’s behaviour), so 16 previously-passing ids of one instance in our slice match no output and every submission to it grades as unresolved.

B Pre-declaration and analysis

The event unit is one (test function, onset observation) pair with parametrised variants collapsed. The gates for proceeding on a substrate were an event rate of at least 0.30 per run and a bearing fraction of at least 25%. Both stacks failed the conjunction (bearing 0% and 16.2%); the gates were then re-declared per (substrate, model stack) before the contrast was unblinded, and no arm reported here is confirmatory. The contrast’s primary endpoint is final-state contamination, paired by instance, exact two-sided sign test; the co-primary is incident exposure. The analysis script was committed before either comparison arm finished. The regression-gated arm was added after the contrast was unblinded and is exploratory. No multiplicity adjustment was planned or applied. Budget exhaustion is scored as failure. Instances whose baseline oracle records failures in the unmodified image are excluded from resolve-rate comparability claims, and their dead tests are typed as missing observations for event counting.

Grading correction between unblindings. The first unblinding of the recovery-policy contrast gave $p = 0.375$ for the primary endpoint: seven cells (five no-recovery, two repair-in-place) had been dropped as ungradable because their final trees made the suite uncollectable. Official grading scores such a patch as failing every test, so the most contaminated states had been dropped from the endpoint they bore on most. The grader now distinguishes an environment failure from a patch that kills the suite, and the seven archived trees were re-graded without re-running any agent.
